Abstract (en)

[origin: EP0445321A1] A desired pulp quality is specified using a quality coefficient (Q^{*}). Suitable quality coefficients are, inter alia, the yield (Y) or the residual lignin concentration (kappa number) of the pulp. A process module (M) is used to determine the digestion temperature (T^{*}) associated with the specified value of the quality coefficient (Q^{*}) as the main control variable. This takes account of the actual values of the concentration of chemicals (C), the digester filling level (L), the production quantity (n) and technology-dependent process constants (a, k, E). The process model can be adapted to match it to altered operating conditions in the pulp digester. For this purpose, at least one of the process constants (k) is redetermined. The actual value of the yield (Y), which is used as quality coefficient, is preferably simulated at least using a spent liquor analysis. Other quantities used for the simulation may be, in particular, the hydromodule (X_a) or the rotary speed of the wood feed means (n₁, n₂, n₃). <IMAGE>
